FFT: Demonstration Application for the Cmpware CMP-DK (Demo Version 2.0 for Eclipse 3.0)

Cmpware, Inc.

Introduction

The *Cmpware Configurable Multiprocessor Development Kit (CMP-DK)* is a multiprocessor simulation and software development environment. It provides fast and efficient modeling of multiprocessor architectures as well as support for software development on such systems. The goal of supporting software development is achieved by providing an interactive, display-rich environment that permits large amounts of information to be displayed in a fast, simple and uncluttered format. Such capabilities are essential in analyzing the behavior of multiprocessor systems.

This demonstration version of the *Cmpware CMP-DK* (version 2.0) for Eclipse 3.0 and higher contains all features of the standard toolkit, but restricts the simulation model to a 3 x 3 heterogeneous array of MIPS32 and SPARC-8 processors. All simulation capabilities and displays are included. This includes:

- Source Code Tracing
 Source Code Variables
 Disassembly
 Memory Display
 Power Estimator
- General Purpose Registers
- Special Purpose Registers
- Command Line Interface
- Link Utilization

Demonstration Applications

Avaliable for use with the *Cmpware CMP-DK* version 2.0 is a series of demonstration applications which are presented to introduce some of the features in the *CMP-DK*. These applications start with small, simple programs gradually building up to more complex applications exploiting relatively low-level parallelism. These demonstrations stand alone and can be studied in any order, but it is best to start with the early examples, which are smaller and simpler and build up to the larger ones. This provides

F	F	Г	A	p	pl	ica	ati	on

a tutorial-like introduction to the features in the Cmpware CMP-DK.

While these demonstrations cover the application development aspects of this tool, much of the power in the *Cmpware CMP-DK* is in the ability to quickly model relatively complex multiprocessor systems. This modeling activity is reserved for licensed copies of the software. For more information on getting licensed copies of the *Cmpware CMP-DK*, contact Cmpware at *info@cmpware.com*.

The groups of files in this tutorial package are as follows:

Introduction - An introduction to all of the applications
 Simple - A simple, single processor test application
 Ping Pong - a simple two processor application
 Hetero - the Ping Pong application on two different types of processors
 FIR Filter - A multiprocessor Finite Impulse Response (FIR) Filter
 AES Encryption - A multiprocessor AES encryption implementation
 FFT Filter - a multiprocessor FFT filter using shared memory
 FFT Filter 2 - a multiprocessor FFT filter using communication channels

These example applications assume that the *Cmpware CMP-DK* has already been successfully installed on your system. For more information on acquiring and installing either the free demonstration version or the fully licensed version, see the Cmpware web site.

The source and compiled code for these demonstration applications can be downloaded from the Cmpware Web site as a compressed ZIP archive at:

http://www.cmpware.com/Apps/CmpwareApps_2_0.zip

The Fast Fourier Transform (FFT) Application

The *Fast Fourier Transform (FFT)* application extends the ideas in the previous example applications. In particular this application builds on the implementation in the FIR filter and AES encryption examples. It is recommended that the FIR filter and AES encryption examples be examined before moving on to the *FFT*. In particular, this application shows the use of Shared Memory as opposed to the standard communication links used in other examples.

The *FFT* code is all in the compressed ZIP archive under the *FFT* directory, and contains source code, Makefile, linker directives file, compiled relocatable object files

and finally, fully linked executable ELF files. In fact, all of the demonstration applications will contain these types of files. All have been built using the *Gnu GCC* compiler with a version higher than 3.0. If you have access to a *MIPS32* compiler which produces standard *ELF* executable with *DWARF2* debug information, you may modify these files and re-compile them and test the results and use them in the *Cmpware CMP-DK*.

Running the Self Hosted FFT Application

The FFT algorithm is used extensively in digital signal processing. It is used to convert time domain signals to the frequency domain where various types of frequency oriented filtering can take place. The FFT algorithm is more compute intensive than the other examples discussed for the *Cmpware CMP-DK* and also tends to have a more complex communication pattern. The details of the FFT algorithm are beyond the scope of this document and will not be covered here, but any standard textbook on digital signal processing should cover the FFT adequately.

The source code for the implementation used in this example is include in the appendicies at the end of this document. The implementation is fairly straight forward and every attempt was made to keep the code simple and readable. Some study of this code may be useful for readers more interested in implementation details. Again, more efficient approaches are possible; this code was intended primarily to be used for demonstration purposes.

As with the other demonstration algorithms, a single processor version of the FFT application is first developed. This approach has several benefits. First, developing a single processor version of any algorithm is typically much easier than building a multiprocessor version. This allows the processes of algorithm design and implementation to be seperated from the process of parallelization. It also creates a 'benchmark' for future compairisons,

Once the algorithm is working correctly, efforts to parallelize it can proceed. Experience has shown that this process is a much simpler path than attempting to simultaneously code and parallelize an algorithm. In particular, debugging is simplified, since the single processor implementation can be tested for logical correctness, then the results of the parallel version can be compared to the results generated by the single processor version.

Figure 1 shows the building and execution of the single processor FFT application. This is compiled and run on a standard workstation, in this case a Linux system. The flag "**-DSELFHOSTED**" is passed to the compiler and is used to indicate that the single

processor is a full development system, in particular, one containing an operating system and display capabilities. This permits the output to be printed to the console as in Figure 1.

Figure 1: The self hosted FFT application.

The source code to this single processor version is in *Appendix E* at the end of this document. Note that this code contains only the main routines. The supporting FFT routines as well as the 32-bit fixed point support is used extensively and can be found in *Appendicies A* through *D*. Note that all of these routines are standard serial, uniprocessor function calls which can be typically found in any text or existing source code for the FFT algorithm implementation.

The output in Figure 1 has five columns and 64 rows of numbers. The first column is

just the integers zero through 63. This is used to graph the X axis of the data. The next two columns are the real and imaginary portions of the FFT data. Only the real portion will be used in the graphing. Finally, the last two columns are the real and imaginary values repeated in hexadecimal format. The format of these values is 16 bits of integral and sixteen bits of fractional data.

Figure 2: The self-hosted FFT filter input and output.

Also included in the source code for the FFT filter are files to graphically plot the output from this execution. If the results of the *fft1.exe* file are piped to a file named *fft.dat*, the *gnuplot* plotting application may be used to graph the output of the FFT to verify that the functionality is correct. These files are supplied in the FFT demonstration directory, including a saved bitmap of the plot.

Figure 2 shows the plot generated with the command:

\$ gnuplot -persist fft.p

This plot shows that the input data is a sine wave going through four cycles with a peak of 100. The FFT filtered output data is a single impulse of height 100 at the value of four on the X axis, as expected.

Figure 3: Loading *fft1.elf* into node (0,0).

Once the FFT filter code for a single processor has been successfully developed in a self-hosted uniprocessor environment, the code may be moved to the *Cmpware CMP-DK* development environment. The first step will be to verify that the uniprocessor code

still operates correctly on the uniprocessor model in the *Cmpware CMP-DK*. Once this is verified, parallelizing the code into a multiprocessor implementation can begin.

Figure 4: *fft1.elf* loaded into node (0,0).

Rather than compiling the code with the standard GCC compiler on the self hosted system, a cross-targeted compiler running on the host system, but generating code for the *MIPS32* processor is used. Additionally, since this embedded *MIPS32* processor does not have dedicated operating system or IO support, the **-DSELFHOSTED** flag is not used. This produces code which sends the FFT results to a pre-specified memory location. The compiled code for a *MIPS32* processor is supplied in the *FFT* directory as *fft1.elf*.

Running the Single Processor FFT Application

To execute this uniprocessor FFT code, the *Cmpware* perspective in Eclipse must first be opened. This is typically done from the Eclipse main menu using the **Window** --> **Open Perspective** --> **Cmpware** menu command. If you have problems getting this view to come up, or have not installed the *Cmpware CMP-DK*, see the installation guide available on the *Cmpware* web site. It will guide you in installing the software.

Figure 5: The single processor *fft1.elf* executing on node (0,0).

The *Cmpware CMP-DK* used in this example is the demonstration version of the software and begins with the default 3 x 3 array of processors. The first row contains three *MIPS32* processors, the second row three *Sparc-8* processors, and the third row

contains another three MIPS32 processors.

Like the previous examples, executable code is loaded into the first processor in the upper left corner of the array. To load this processor with executable code, select the processor with the mouse. It should be highlighted with a grey background and the **Status** window at the bottom should indicate that the processor **MIPS32(0,0)** is selected.

Figure 6: The Cmpware CMP-DK Preferences page.

Use the **Load** button (\geqq) to bring up a file selection dialog. Using this file selection dialog, select the *fft1.elf* file from the list of files for the *FFT* demonstration as shown in Figure 3. A message in the **Status** window at the bottom of the IDE should indicate that the file was successfully loaded into the MISP32 processor at location (0,0) as in

Figure 4.

At this point, the executable file *fft1.elf* is loaded into the processor in the upper left corner of the processor array. Clicking on the **Step** button (\square) advances the global clock in the simulation and updates the displays in the *Cmpware CMP-DK*. In the view in Figure 5, the multiprocessor has been stepped through 13 cycles, as indicated by the **Status** window.

Figure 7: The single processor FFT results in local memory.

For larger applications such as the FFT filter, the single stepping with the **Step** button (\square) one cycle at a time quickly becomes tedious. The *Cmpware CMP-DK* is designed to permit a configurable step size for the simulation. This allows larger sections of code to be executed with a single step.

Like most parameters in the Cmpware *CMP-DK* the step size is set in the Cmpware **Preferences Page**. This is set from the menu items **Windows --> Preferences**. This brings up the **Preference** dialog box in Figure 6. Selecting **Cmpware** from the list on left brings up the preferences for the *Cmpware CMP-DK*. In this case, the step size is set to 1000. Pressing the **[Ok]** button will accept this value.

Now when the **Step** button (\square) is pressed, the simulation steps 1000 cycles and the display updates. This coarser display granularity permits simulation to proceed at a faster pace. Note that the simulation may be suspended and the displays updated before 1000 cycles if a breakpoint, illegal opcode or other system error occurs. Also note that this parameter is also used by the **Run** button (\bigstar). Steps of 1000 are used between display updates. This sets the 'speed' of the 'animated' display.

At this point it is useful to switch to the main **Memory** display and scroll down to address 0x00003000 as in Figure 7. This is the address in the source code where the results will be placed. Stepping the simulation, a block of data identical to those printed in the self hosted version can be seen being written to the memory. Note that this was the primary reason for printing the hexadecimal values in the self-hosted version. it makes it easier to compare to results to the ones displayed in the **Memory** view.

While the execution can be single stepped until new values appear in the memory display, a breakpoint could be set in the **Source Code** window. This is done by clicking on the vertical bar to the left of the source code text. A small round blue icon (•) should appear along with a message in the **Status Window** indicating that the breakpoint was set.

Using the **Run** button (\bigstar), the simulation should execute until the breakpoint is reached. The breakpoint may be removed by clicking on the breakpoint icon to the left of the source code. A message in the **Status Window** should indicate that the breakpoint was removed.

Inspecting the results at address 0x00003000 in the **Memory** display window, it is clear that the FFT filter is indeed functioning correctly on the *MIPS32* model and generating the correct results.

Parallelizing the FFT Application

The *Cmpware CMP-DK* supports a wide variety of inter-processor communication mechanisms. The default network configuration for the demonstration software is a 2D torus, which is just a 2D nearest-neighbor grid with the ends folded around on itself.

FFT	App	lication
<u></u>		

This folding makes the topology a 'doughnut', but mostly just serves to keep the network from having any dangling ends.

The nearest neighbor torus communication consists of a shared block of memory and bi-directional *Shared Register* communication channels. These Shared Registers are 32 bit data registers memory mapped at some address in the memory space. They are also fully synchronized, meaning that no data will be written to a Shared Register until any previously written data is read out. And no data will be read until data has been made available by a write. If reads or writes cannot be performed, the processor stalls. This can be thought of as a one word FIFO. Such communication channels may also be found in theoretical models such as *Communicating Sequential Processes* (CSP). These types of channels have the useful feature that they are easy to debug and analyze.

Unlike the previous examples, the FFT will make use of shared memory to send data from one processor to another. While links provide built-in synchronization when sharing data between processors, shared memory does not. There are several popular techniques for synchronizing access to shared memory in multiprocessing situations. One is to use the 'test and set' or semaphore instruction found in many processors. Unfortunately, this instruction is not necessarily found in all processors. Additionally, it is not supported directly in programming languages such as "C". This would mean writing assembly language, which would make this application more difficult to port to new processors.

The solution chosen for this implementation is to use a combination of shared memory and Shared Register links. Because the Shared Register links are synchronized, they function almost identically to a semaphone. The processor can wait on a link until the sending processor has finished writing to memory, providing the necessary control.

Note that this aspect of multiprocessing is very important and should be understood thoroughly before programming multiprocessors. Not only must data be sent to the correct processor, but care must be taken to be sure the receiving processor reads the data only *after* it has been written. Attempting to read data from a processor too early will typically result in undefined values being read in and undefined program behavior.

Such coding errors can be difficult to identify. While conventional wisdom often indicates that writing multiprocessor code for shared memory systems is somehow easier than for other architectures, it does require extra care in synchronizing data. And if this synchronization is not performed correctly, the resulting errors can be difficult to track down. The actual software implementation of the shared memory communication will be discussed more in the next section of this document.

The software definitions in the CmpwareTorus.h include file describe these

Figure 8: The FFT running on two nodes.

As in the other examples, these registers and shared memories exist in the processor memory map and they can be accessed in high level languages as a simple address pointer. No new language constructs or libraries are required. The source code in *Appendicies* demonstrate how communication across processors is performed by a simple assignment to or from address pointers.

Because of this pointer access to the communication channels and shared memories, it

becomes fairly simple to parallelize this code from the *fft1.c* serial version. The regular serial functions in *fft.c* and *fixed32.c* do not need to be modified at all. These will be executed in parallel across two or more nodes to calculate the final result in parallel. All that is required is that intermediate results, rather than being sent to a local variable, get sent to the next processor for the next stage of processing.

Figure 9: The two node FFT implementation results.

The main loop in the *fftN.c* source code in *Appendix G* is very similar to the single processor code. All that has changed is that partial result inputs now come from a pointer to a shared memory block and are sent to another pointer to a shared memory block. There are some other features of this code, but these will be discussed after the demonstration of the code executing.

As shown in Figure 8, executable code must be loaded into the three *MIPS32* processors in the top row. Again this is done using the **Load** button (\succeq) to bring up a file selection dialog. The executable *ELF* files are then selected and loaded. In this application, the first processor at (0,0) is loaded with *fft0.elf*. The next two processors, (0,1) and (0.2) are loaded with the *fftN.elf* executable file. It is very important that each of these files is loaded into the correct processor with no other operations performed in the interim.

Unlike the uniprocessor versions of this software, the synchronous communication of the FFT application will permit the processors to begin execution when data is available, and stop execution, or at least stall, when no further data is available. The only involvement of processor (0,0) in the calculation is to send data to the next two processors. These two processors split up the task of performing the FFT calculation.

Execution may be controlled either manually with the **Step** button (\square) or as an animation with the **Run** button (\bigstar). The end of execution will be obvious from the main **CMP Array** window. When all of the top row of processors are 'greyed' and no longer progressing in execution, the calculation is complete. If the **Run** button (\bigstar) was used, the **Stop** button (\blacksquare) should be used to halt execution at this point.

Figure 9 shows the **Memory** view in processor (0,2) after execution has completed. This is exactly the results from the single processor code, as expected. This can be compared to the results in either the self hosted or the single processor version of the FFT.

Figure 10 shows an six processor version of the FFT algorithm. This is not available with the demonstration version of the *Cmpware CMP-DK* and can only be executed on a licensed version of the software. A glance at the **Power Meter** view indicates that even at six processors, the utilization remains as high as 98% and a large amount of processing in parallel occurs. And as with the two node version, longer runs will increse these numbers for all processors into the mid-90% range.

What is perhaps more interesting is that fairly low level parallelism is easily extracted and put to use in a single chip multiprocessor using existing tools and simple software techniques. In this example, a 64 point FFT is computed. The number of stages is determined by this value. The number of 'stages' of the FFT algorithm is the base two logarithm of the number of points in the FFT. I this case, the number of stages is six. Larger FFTs can use more processors, but only growing logarithmically with this approach. Additionally, it may be possible to exploit more parallelism within a stage. This is left as an exercise for the reader.

And as with the previous examples, it is also possible to calculate more than one stage

per processor. So in this example, from one to six processors can be effectively employed. It is also interesting to point out that this allocation happens completely at run time and that no changes to the original *fftN.c* code have to be made. All that is required is that the parameter giving the number of processors in *fft0.c* be changed to the appropriate value.

Shared Memory and the FFT Application

In the general case, using shared memory in a multiprocessor requires special care. Data cannot simply be written to and read from shared memory at will. There must be some form of 'handshaking' or synchronization between processors when data is

transferred. This permits two specific problems from occurring. The first is data being read from an address before the writing processor has had the chance to write the value. This results in incorrect data being read. The other is data being overwritten before the reading processor has had a chance to read the data. Some mechanism must be used for the writing processor to tell the reading processor when data has been written to a shared memory resource and another mechanism must be in place to tell the writing processor that the data has been read and the address may be re-used.

```
/* On the first stage shuffle in from shared memory */
/* else shuffle from local temp to local temp */
if (stage == firstStage) {
   wait = *in; // Wait for data in shared memory
   shuffle(inmem, t2, fftSize);
   *in = 1; // Finished with shared memory
} else
   shuffle(t1, t2, fftSize);
```

Figure 11: Synchronizing shared memory.

Figure 11 shows a small piece of code where data is 'shuffled' in from a shared memory as the variable inmem and written out to a local memory as the temporary variable t2. In this implementation the Shared Register port in is used to provide the synchronization. In this case, what data is sent over the Shared memory links is irrevelant; the data is never used. The channel is used solely for control to provide synchronization.

In this case, the processor waits for data to arrive at the *in* port indicating that the block of shared memory at *inmem* can be accessed. The processor now 'owns' this piece of shared memory, by convention. When the reading of the shared memory via the *shuffle()* call is complete, the processor sends a message back to the writing processor via the *in* port indicating that it is done reading the *inmem* buffer. In this application, this indicates that the next block of FFT data can be sent for processing.

In general, shared memory accesses are bracketed by such controls. Exclusive access to the memory is established, the data in the shared memory is used, and the shared memory is released for re-use. Of course, this protocol must be followed by the other processors participating in the transaction. Code performing a similar function is used in the writing processor.

Again, note that just arbitraribly access shared memory is not sufficient to guarantee correct results in a multiprocessor. It may be possible to get 'lucky' and have the

correct values always be provided at the correct time. But such code is inherently unstable and unreliable. Also note that there are other languages and tools to help manage shared memory in these sorts of applications. There is a vast body of literature on this subject which the interested reader may begin to explore by starting with any introductory text in parallel processing.

Conclusions

The *Cmpware CMP-DK* is a rich display environment combining fast simulation and flexible multiprocessor modeling. This makes it an ideal environment for architecture modeling and software development for these systems.

While the execution and display features of the *Cmpware CMP-DK* are notable, much of the power of the system lies in its ability to quickly and flexibly construct processor, network, link and multiprocessor models. This modeling capability is a large part of the commercial version of the *Cmpware CMP-DK*.

For more information on the commercial version of the *Cmpware CMP-DK* see our web site at:

http://www.cmpware.com/
